

# Local Algorithms for Finding a Missing String

**MISSING STRING:** Given a list of  $M$  strings of length  $N$  ( $M < 2^N$ ), find a string not on the list

Cantor's Diagonal Argument shows:

If  $M \leq N$ , then we can find a missing string by taking the diagonal of the list

$N$

	1	2	3	...	k	...
$x_1$	1	0	1		0	
$x_2$	1	0	1		1	
$\vdots$						
$x_k$	1	0	0		1	
$\vdots$						

$M$

# Local Algorithms for Finding a Missing String

**MISSING STRING:** Given a list of  $M$  strings of length  $N$  ( $M < 2^N$ ), find a string not on the list  
If the list is truth tables of “easy” functions, we are asking you to find a “hard” function!

Cantor’s Diagonal Argument shows:

If  $M \leq N$ , then we can find a missing string by taking the diagonal of the list

		$N$					
		1	2	3	...	k	...
$M$	$x_1$	0	0	1		0	
	$x_2$	1	1	1		1	
	$\vdots$						
	$x_k$	1	0	0		0	
	$\vdots$						

For all  $i = 1, \dots, N$ , we can obtain the  $i$ -th bit of a missing string with **only one bit probe** into the input [probe the  $i$ -th bit of the  $i$ -th string, output the opposite bit]

**That is, when  $M \leq N$ , there’s a “1-probe” algorithm for MISSING STRING**

**Under what conditions can we use only  $k$  probes? (Why?)**

# Local Algorithms for Finding a Missing String

**MISSING STRING:** Given a list of  $M$  strings of length  $N$  ( $M < 2^N$ ), find a string not on the list

If  $M \leq N$ , then we can find a missing string by taking the diagonal of the list

For all  $i = 1, \dots, N$ , we can obtain the  $i$ -th bit of a missing string with **only one bit probe**  
*That is, there is a “1-probe” algorithm for MISSING STRING*

*What can we do with  $k$  probes?*

**Theorem 1 (easy):** For  $M = kN$ , there is **no  $k - 1$**  probe algorithm for MISSING STRING.

**Proof:** Suppose for **each  $i = 1, \dots, N$ ,**

your algorithm makes only  $k - 1$  probes and computes a missing string  $y$ .

The total number of different strings you probed, over all  $i$ , is  $\leq (k - 1)N < M$ .

So there's some string on the list you haven't probed at all.

Your algorithm fails on every input that includes  $y$  among those non-probed strings.

# Local Algorithms for Finding a Missing String

**MISSING STRING:** Given a list of  $M$  strings of length  $N$  ( $M < 2^N$ ), find a string not on the list

**Theorem 2:** For  $M \leq kN$ , there is an  $O(k \log k)$ -probe algorithm for MISSING STRING.

**Idea:** Combine the diagonal argument and the algorithm that makes  $O(M)$  probes!

Divide the  $N$  bits of each string into  $\sim N/b$  blocks of length  $b$   
Divide the  $M$  strings into  $\sim M/t$  blocks of length  $t$ , where  $t \leq 2^b - 1$ .

If  $\frac{M}{t} \leq \frac{N}{b}$ , then if we find a missing string for each purple block,

their concatenation is a missing string for the entire set!

Have:  $M = kN$ , Want:  $M \leq (2^b - 1) N/b$ . We therefore set:

$$b = \log(k) + \log\log(k) + O(1)$$

Then, to get any particular bit of the missing string, number of probes is

$$O(t) \leq O(2^b) \leq O(k \log k)$$

# What Good are Local Algorithms?

Theorem 2: For  $M \leq kN$ , there is an  $O(k \log k)$ -probe algorithm for MISSING STRING.

Corollary: New Time Hierarchy Theorems, against Non-Uniform Programs!

**Time Hierarchy Theorem:** For “reasonable”  $g, h$  where  $h(n) \gg g(n)$ ,  
 $\text{TIME}(h(n)) \not\subseteq \text{TIME}(g(n))$

The time hierarchy can be generalized to work for “small non-uniform advice”

Define  $f \in \text{TIME}[g(n)]/a(n)$  if for every  $n$ , there is *some program* of length  $a(n)$ ,  
running in time  $g(n)$ , that decides  $f$ .

**Time Hierarchy Against Advice [Folklore]:** For “reasonable”  $g, h$  where  $h(n) \gg g(n)$ ,  
 $\text{TIME}(h(n)) \not\subseteq \text{TIME}(g(n))/n$

Idea: The hard function running in  $O(h(n))$  time  
treats its input of length  $n$  *as a program*, and simulates  
the program on its own code, outputting the opposite answer.

contains uncomputable stuff!

# What Good are Local Algorithms?

Theorem 2: For  $M \leq kN$ , there is an  $O(k \log k)$ -probe algorithm for MISSING STRING.

Corollary: New Time Hierarchy Theorems, against Non-Uniform Programs!

**Time Hierarchy Theorem:** For “reasonable”  $g, h$  where  $h(n) \gg g(n)$ ,  
 $\text{TIME}(h(n)) \not\subseteq \text{TIME}(g(n))$

The time hierarchy can be generalized to work for “small non-uniform advice”

Define  $f \in \text{TIME}[g(n)]/a(n)$  if for every  $n$ , there is *some program* of length  $a(n)$ ,  
running in time  $g(n)$ , that decides  $f$ .

**Time Hierarchy Against Advice, Version 2 [Folklore]:** For “reasonable”  $g, h$   
 $\text{TIME}(2^{n+g(n)} \cdot h(n)) \not\subseteq \text{TIME}(h(n))/g(n)$

Idea: The hard function enumerates all  $2^{g(n)}$  programs of length  $g(n)$ ,  
and simulates each of them on every possible  $n$ -bit input.

Then it computes a missing string from the list of  $M = 2^{g(n)}$  strings of length  $N = 2^n$

# What Good are Local Algorithms?

Theorem 2: For  $M \leq kN$ , there is an  $O(k \log k)$ -probe algorithm for MISSING STRING.

Corollary: New Time Hierarchy Theorems, against Non-Uniform Programs!

**Old Time Hierarchies Against Advice:** For “reasonable”  $g, h$  where  $h(n) \gg g(n)$ ,

$$\text{TIME}(h(n)) \not\subseteq \text{TIME}(g(n))/n \quad \text{TIME}(2^{n+g(n)} \cdot h(n)) \not\subseteq \text{TIME}(h(n))/g(n)$$

**New Hierarchy Against Advice [informally]:** for  $g(n) \geq n, h(n) \geq n$ ,

$$\text{TIME}(2^{g(n)} \cdot g(n) \cdot h(n)/2^n) \not\subseteq \text{TIME}(h(n))/g(n)$$

Finding a function **not** in  $\text{TIME}(h(n))/g(n)$  amounts to finding a missing string of length  $N = 2^n$  from a list of  $M = O(2^{g(n)})$  strings [all programs of length  $g(n)$ ] where any particular bit of any particular string can be determined in  $O(h(n))$  time.

For  $k = 2^{g(n)-n}$ , we have  $M \leq kN$ . Thus we can compute any bit of some missing string, probing  $O(k \log k) \leq O(2^{g(n)-n} \cdot g(n))$  bit positions, each probe taking  $O(h(n))$  time.

# What Good are Local Algorithms?

Theorem 2: For  $M \leq kN$ , there is an  $O(k \log k)$ -probe algorithm for MISSING STRING.

Corollary: New Time Hierarchy Theorems, against Non-Uniform Programs!

## Some New Hierarchies:

$$\text{TIME}(5^n) \not\subseteq \text{TIME}(2^n)/(2n)$$

$$\text{TIME}(n^{2c+1}) \not\subseteq \text{TIME}(n^c)/(n + c \log(n))$$

$$\text{TIME}(2^{cn} \cdot \text{poly}(n)) \not\subseteq \text{TIME}(O(n))/(cn + n)$$

**Note: All the above hierarchies relativize,  
and there is an oracle  $A$  such that  $\text{TIME}^A[2^{cn}] \subseteq \text{TIME}^A[O(n)]/(cn + n) !!$**

# (Main) Open Problems

- Does MISSING STRING have small uniform depth-3 circuits, or not?  
(it cannot have depth-2 circuits, and it does have depth-4 circuits)
- How many probes (as a function of  $k$ ) are necessary and sufficient to find a missing string, when  $M \leq kN$ ?  
The answer is somewhere between  $k$  and  $O(k \log k)$
- More connections between MISSING STRING and lower bounds?

# How to Prove Lower Bounds With Algorithms

## Lecture 4: The Power of Constructing Bad Inputs

(based on work with Lijie Chen, Ce Jin, and Rahul Santhanam, FOCS 2022)

# Lower Bounds are Hard to Prove

There are many barriers

- Relativization [Baker-Gill-Solovay, 70's]
- Natural Properties [Razborov-Rudich, 90's]
- Algebrization [Aaronson-Wigderson, 00's]

**Summary:** The standard methods that we use to reason about generic computation cannot resolve  $P \neq NP$  (or  $P \neq PSPACE$ , or  $EXP \neq ZPP$ , or  $NEXP \neq BPP$ , etc.)

**We apparently know a lot about what strong lower bounds CANNOT look like.** We know many limitations on how such proofs must proceed.

# What *could* a proof of $P \neq NP$ look like?

We seem to know a lot about what a proof of  $P \neq NP$   
(and  $P \neq PSPACE$ ,  $EXP \neq ZPP$ ,  $NEXP \neq BPP$ , etc.)  
*cannot* look like...

... can we identify properties that such lower  
bound proofs *must* possess?

**What properties are missing from lower bounds we  
know how to prove, which we will *have* to include  
in a proof of  $NEXP \neq BPP$  (or any of the above)?**

# What *could* a proof of $P \neq NP$ look like?

Let  $f: \{0,1\}^* \rightarrow \{0,1\}$  and let  $\mathcal{A}$  be a class of algorithms.

A lower bound " $f \notin \mathcal{A}$ " is a claim of the form:

$$(\forall A \in \mathcal{A})(\exists^\infty n)(\exists x_A \in \{0,1\}^n)[A(x_A) \neq f(x_A)]$$

Fix a lower bound problem  $f \notin \mathcal{A}$ , and fix an algorithm  $A$ .  
What is the *complexity* of constructing a "bad"  $x_A$  of length  $n$ ?

The literature on lower bounds gives roughly two types of answers:

1. **"Random" or non-constructive ways of choosing  $x_A$**   
Proofs relying on counting/information-theoretic arguments
2. **"Efficient" ways of choosing  $x_A$**   
Proofs based on diagonalization arguments

# What *could* a proof of $P \neq NP$ look like?

Our starting inspiration is from [Gutfreund-Shaltiel-Ta Shma'05]

**If  $P \neq NP$ , then**

**“bad inputs to SAT algorithms can be efficiently constructed”.**

The following theorem can be derived from their paper:

For every  $n^k$ -time algorithm  $A$ ,

there is an algorithm  $R_A$  that for *infinitely many*  $n$ ,  $R_A(1^n)$  outputs a formula  $F_n$  of length  $n$  such that  $F_n$  is SAT  $\Leftrightarrow A(F_n) = 0$ .

refuter  
[K'00]

Furthermore,  $R_A$  runs in  $n^{O(k^2)}$  time.

# Gutfreund-Shaltiel-Ta Shma '05

If  $P \neq NP$ , then for infinitely many input lengths,  
“bad inputs to SAT algorithms can be efficiently constructed”

Let's start by getting a refuter for an  $n^k$ -time algorithm  $A$  trying to print SAT assignments, when they exist. (It first attempts to print a SAT assignment, and outputs UNSAT if that assignment fails to satisfy.)

All bad inputs are satisfiable formulas on which  $A$  prints UNSAT

$R_A(1^n)$ : Construct a formula  $F_n$  encoding the property:

$n^{O(k)}$  size

$(\exists G. |G| = n \text{ and assignment } a)[G(a) = 1 \wedge A(G) \text{ outputs UNSAT}]$

Run  $A$  on  $F_n$ . If  $A$  prints some  $G'$ , then output  $G'$  else output  $F_n$

We are asking  $A$  to print its own counterexamples  $G'$ . If  $A$  does this for  $\infty$  many  $n$ , then we are done. If  $A$  does not do this for  $\infty$  many  $n$ , then  $\{F_n\}$  is printed for almost every  $n$ . This set contains  $\infty$  many counterexamples, because we assumed  $P \neq NP$ .

# Gutfreund-Shaltiel-Ta Shma '05

If  $P \neq NP$ , then for infinitely many input lengths,  
“bad inputs to SAT algorithms can be efficiently constructed”

Getting a refuter for an  $n^k$ -time algorithm  $A$  trying to **decide** SAT:

$R_A(1^n)$ : Construct a formula  $F_n$  encoding the property:

$(\exists G, |G| = n \text{ and assignment } a)[G(a) = 1 \wedge A(G) \text{ outputs UNSAT}]$

Use search-to-decision on  $A$  to search for a SAT assignment to  $F_n$ .

(Try setting a variable  $x$  to 0, then as 1, seeing what  $A$  reports...)

Cases: (1)  $A(F_n) = \text{“UNSAT”}$ . Then output  $F_n$

(2) We find a SAT assignment  $G'$ . Then output  $G'$

(3) We find a subformula  $F''$  such that  $A(F'') = \text{“SAT”}$ ,

but  $A(F''[x = 0]) = A(F''[x = 1]) = \text{“UNSAT”}$

In case (3),  $A$  is wrong on at least one of the 3 subformulas!

Can report the set as “bad”. (To get an  $R_A$  so that only one is reported, consider three different algs  $R_A^1, R_A^2, R_A^3$  such that  $R_A^i$  reports the  $i$ -th)

# What *could* a proof of $P \neq NP$ look like?

Our starting inspiration is from [Gutfreund-Shaltiel-Ta Shma'05]

**If  $P \neq NP$ , then**

**“bad inputs to SAT algorithms can be efficiently constructed”.**

The following theorem can be derived from their paper:

For every  $n^k$ -time algorithm  $A$ ,

there is an algorithm  $R_A$  that for *infinitely many*  $n$ ,  $R_A(1^n)$  outputs a formula  $F_n$  of length  $n$  such that  $F_n$  is SAT  $\Leftrightarrow A(F_n) = 0$ .

refuter  
[K'00]

Furthermore,  $R_A$  runs in  $n^{O(k^2)}$  time.

Say **there is a  $P$ -constructive separation of  $f \notin \mathcal{A}$**

if for all  $\mathcal{A}$ -algorithms  $A$ , there is a poly-time algorithm  $R_A$  which (for  $\infty n$ ) given  $1^n$  can output  $x_A$  such that  $A(x_A) \neq f(x_A)$ .

[GST'05]  **$P \neq NP \Rightarrow$  There's a  $P$ -constructive separation of SAT  $\notin P$**

# Constructive Separations

There is a  $P$ -constructive separation of " $f \notin \mathcal{A}$ "

if for all  $\mathcal{A}$ -algorithms  $A$ , there is a poly-time algorithm  $R_A$  which (for  $\infty n$ ) given  $1^n$  can output  $x_A$  such that  $A(x_A) \neq f(x_A)$ .

[GST'05]  $P \neq NP \implies$  There's a  $P$ -constructive separation of  $SAT \notin P$

Which lower bound problems *require* constructive separations, and which do not?

This is an algorithmic question about the nature of the lower bound. What *algorithms* are implied by separations?

# We Argue: Constructive Separations Are Key!

**1. Essentially all open separation problems regarding polynomial time *require* constructive separations**

**Thm: For all  $C \in \{P, ZPP, BPP\}$  and  $D \in \{NP, PSPACE, EXP, NEXP, \dots\}$   
If  $C \neq D$  then there is a  $C$ -constructive separation of  $C \neq D$ .**

**2. Making many *known* lower bounds constructive, implies major lower bounds!**

More examples of how algorithms can imply lower bounds!

**Example 1: [Maass 84] PALINDROMES  $\notin$   $NTIME1[o(n^2)]$ .**

**Thm: Making Maass' lower bound  $P$ -constructive implies  $TIME(2^{O(n)})$  contains functions of exponential circuit complexity. "Constructivizing" this lower bound implies universal derandomization! [IW97]**

**Therefore, "constructivity" is a property we *want* of lower bounds!**

## 2. Making many *known* lower bounds constructive, *requires* resolving other major lower bound problems

### Example 2: Randomized streaming algorithm lower bounds.

Many problems (including simple ones like DISJOINTNESS) are well-known to require  $\Omega(n)$ -space randomized streaming algorithms

**Thm:** For any  $\Pi \in NP$ , a  $P^{NP}$ -constructive separation of  $\Pi$  from  $(\log n)^{\omega(1)}$  space randomized streaming algs implies  $EXP^{NP} \neq BPP$ .

### Example 3: Randomized query lower bounds.

Promise-MAJORITY: distinguish bit strings with  $> \frac{1}{2} + \epsilon$  ones from strings with  $< \frac{1}{2} - \epsilon$  ones. Well-known to require  $\Theta\left(\frac{1}{\epsilon^2}\right)$  queries.

**Thm:** A “uniform  $AC^0$ ”-constructive separation of Promise-MAJORITY from randomized query algorithms using  $o\left(\frac{1}{\epsilon^2}\right)$  queries and  $poly\left(\frac{1}{\epsilon}\right)$  time implies  $P \neq NP$ .

Many more results in the paper...

# Constructive Separation of $P \neq PSPACE$

**Thm:** If  $P \neq PSPACE$  then there is a  $P$ -constructive separation of  $P \neq PSPACE$

**Proof Idea:** Instead of SAT, look at TQBF (true quant. Boolean formulas)

Getting a refuter for an  $n^k$ -time algorithm  $A$  trying to **decide** TQBF:

$R_A(1^n)$ : Construct a formula  $F_n$  encoding the property:

$$(\exists \text{ QBF } "(Qx)G(x)" \rightarrow |G| = n)$$

where  $G$  itself is a QBF,  $Q \in \{\exists, \forall\}$

$$[\text{either } A((\forall x)G(x)) \neq A(G(0)) \wedge A(G(1)) \\ \text{or } A((\exists x)G(x)) \neq A(G(0)) \vee A(G(1))]$$

$A$  is inconsistent on these three

Cases: (1)  $A(F_n) = \text{"false"}$ . Then output  $F_n$

In general, we just need a "downward self-reduction"

(2)  $A(F_n) = \text{"true"}$ . Try using search-to-decision to find

" $(Qx)G(x)$ ". Either this fails (in which case you get 3 bad formulas) or it succeeds, but then one of  $(Qx)G(x)$ ,  $G(1)$ ,  $G(0)$  must be wrong!

Can report set of 3 as "bad". (Can also modify  $R_A$  to only report one)

# Making One-Tape TM Lower Bounds Constructive?

[Maass 84] PALINDROMES  $\notin NTIME1[o(n^2)]$ .

Thm: Making Maass' lower bound  $P$ -constructive implies that  $E$  contains functions of circuit complexity  $> 2^{\epsilon n}$  for some  $\epsilon > 0$

Proof Sketch: We make a nondeterministic one-tape TM  $M$  that takes  $N^{1+O(\epsilon)}$  time and correctly decides all palindromes of length  $N = 2^n$  with circuit complexity  $< 2^{\epsilon n}$ .

Therefore, any  $P$  algorithm that (on  $1^n$ ) prints a “bad” input for  $M$  must print a **hard function**. (The consequence follows by padding.)

$M$  guesses a circuit  $C$  of size  $N^\epsilon$  encoding the input  $x$ , and guesses  $|x|$ . “Dragging along” the description of  $C$  as it reads the bits of  $x$ , it verifies the truth table of  $C$  equals  $x$ . It verifies  $x$  is a palindrome by using  $C$  to check that the bits of the 2<sup>nd</sup> half of  $x$  match the 1<sup>st</sup> half, and it uses  $|x|$  to determine when to start checking the 2<sup>nd</sup> half.

# Some Open Questions

- Relativization tells us that “direct” diagonalization-based proof methods are limited...  
But any major separation against  $P$  (or  $BPP$ , or  $ZPP$ ) will **require** a key property of diagonalization-based proofs: *the ability to efficiently produce “bad” inputs.*  
What other methods of proof could yield this consequence?
- What about separations against LOGSPACE? NC? ACC0?  
E.g. Does  $NP \neq LOGSPACE$  imply a constructive separation?
- Are there **equivalences** between “derandomization” and constructive separations based on the probabilistic method?

Thank you!
